ON THE SEARCH FOR CONDITIONS FOR PRODUCTION PROCESS OPTIMIZATION

Małgorzata Szerszunowicz

Abstract. The experimental design methodology mainly deals with the estimation of a usually unknown response surface function. An important problem in the field of design of experiments is to determine the number of experimental trials, taking into account certain limitations resulting from the nature of the manufacturing process. The experimental design methodology also includes – as if a separate section – methods of searching for conditions for the optimization of processes and the optimal design of experiments.

The aim of this paper is to present a method of searching for conditions for manufacturing process result optimization. The proposed method uses non-classical statistical methods and is presented for selected empirical data.

1. Introduction

The elements of the theory of design of experiments were first introduced at the beginning of the 20th century by R.A. Fisher in agricultural experiments. The results obtained at that time made it possible to use the experimental design methodology in many areas of science, inter alia biology, medicine, chemistry, engineering and statistical quality control (Ryan 2007).

Design of experiments, which has applications in production companies, allows one to improve technological and economic results of the production process. The theory of the optimization of design of experiments in particular plays an important role in practice and is extensively described in specialist literature (Puckelsheim 1993; Silvey 1980; Ryan 2007).
The purpose of this paper is to present a method of searching for optimal conditions for manufacturing processes and its application. The aim of this research is to limit the number of experimental trials of design of experiment, which contributes to decreasing the cost of the experiment.

2. The theoretical basis for design of experiments

The application of the methods of design of experiments in statistical quality control leads to determining the factors which most significantly affect the variable characterizing the investigated process as well as allows to specify the values of factors for which result variable reaches the desired value or the smallest variability.

The use of design of experiments while preparing the production process is connected with a detailed formulation of the problem and the proper selection of factors and response variable characterizing the process under study. Moreover, one ought to determine the number of experimental trials and take into account the possible randomization restrictions. Then, after performing the experiment, one should analyze the results and formulate conclusions and recommendations for the process under study (Montgomery 1997).

The experiment is a sequence of $n$ successive experimental trials which are a single result of the value of response variable $Y$, with the fixed values of $X_1, X_2, \ldots, X_m$ specified on sets $X_1, X_2, \ldots, X_m$ respectively. The experimental area is a set of points $x = (x_1, x_2, \ldots, x_m)$, where $x_i \in X_i, i = 1, 2, \ldots, m$.

Then the set of pairs $P_n = \{x_j, p_j\}_{j=1}^n$ is a design of experiment with $n$ experimental trials, where $x_j = (x_{j1}, x_{j2}, \ldots, x_{jm})$ and $p_j = \frac{n_j}{n}$, where $n_j$ is the number of experimental trials in point $x_j$ of the experimental area, and also $\sum_{j=1}^n n_j = n$ and $\sum_{j=1}^n p_j = 1$ for $j = 1, 2, \ldots, n$. The relationship between the set of factors and the response variable characterizing the process in the best way is presented in the form of the following statistical model (Wawrzynek 1993):

$$Y(X_1, X_2, \ldots, X_m) = y(X_1, X_2, \ldots, X_m) + \varepsilon,$$

where $EY(X_1, X_2, \ldots, X_m) = y(X_1, X_2, \ldots, X_m)$, $E\varepsilon = 0$ and $V\varepsilon = \sigma^2$, where $\sigma^2$ is a constant value, independent of the values of the factors. This model
can be presented as a general linear model (Wawrzynek, 2009) \( Y = F\beta + \varepsilon \), where

\[
Y^T = \begin{pmatrix} Y_1 & Y_2 & \ldots & Y_n \end{pmatrix} \\
\varepsilon^T = \begin{pmatrix} \varepsilon_1 & \varepsilon_2 & \ldots & \varepsilon_n \end{pmatrix} \\
\beta^T = [\beta_1, \beta_2, \ldots, \beta_k] \\
f^T(x) = (f_1(x), f_2(x), \ldots, f_k(x))
\]

and \( f_j(x_j) \equiv x_{ij} \), for \( i = 1,2,\ldots,k \), \( j = 1,2,\ldots,n \). Then the response surface function is defined as a formula \( y = F\beta \). The realization of the classical design of experiments leads to the estimation of parameters of response surface function defined as (Wawrzynek, 2009)

\[
y(x) = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_m x_m + \beta_{12} x_1 x_2 + \ldots + \beta_{12\ldots m} x_1 x_2 \ldots x_m.
\]

The estimation of the parameters of a response surface function is usually carried out with the use of the least squares method. The use of this method depends on certain assumptions being fulfilled, which in the case of many different production processes cannot always be ensured (Montgomery 2001). Then, in order to estimate the parameters of the response surface function, one may use the bootstrap method of the estimation of response surface function (Szerszunowicz 2014).

3. The theory of the optimization of design of experiments

The experimental design methodology is not limited only to issues of the analysis of variance or problems of the analysis of regression. An important issue in the theory of design of experiments is the optimization of design of experiments. One may understand the theory of the optimization of design of experiments in two ways: as the search for conditions for the optimization of product quality and as the optimal design of experiments.

The search for conditions for the optimization of product quality consists in describing the values of factors for which the response surface func-
tion reaches the appropriate value. The most frequently used methods of the optimization of product quality are (Wawrzynek 2009):

- Box–Wilson method
- Evolutionary Operation (EVOP)
- Taguchi methodology.

The abovementioned methods require the following: fulfillment of some assumptions and the use of some elements of differential calculus (Box–Wilson method); numerous experimental trials with small changes in the levels of the process operating variables (EVOP); and determination of the appropriate orthogonal arrays (Taguchi methods). In practice, the realization of the abovementioned methods of optimization may be impossible or too time-consuming (prolonged duration of production processes), which significantly influences their economical results.

Optimal design of experiments consists in choosing the proper design of experiment which is the best one according to a certain optimality criterion. The most popular criteria are (Ryan 2007):

- D-optimality criterion;
- G-optimality criterion;
- A-optimality criterion.

The theory of optimal design of experiments is widely described in specialist literature by F. Puckelsheim (1993) and S.D. Silvey (1980), among others. Over the years, the optimality criteria have received criticism because of practical reasons (Ryan 2007).

4. The method of the search for conditions for process optimization and its application

Within specialist literature, there have been a few publications taking into account design of experiment realization costs (Joiner and Campbell 1976; Draper and Stoneman 1968; Ryan 2007). The present article discusses the issue of the search for conditions for the optimization of product quality with particular reference to the economic aspect of manufacturing processes.

4.1. The proposed method

Let us assume a design of experiment which takes into account $m$ factors occurring at $n_i$, $i = 1, 2, \ldots, m$ levels. Also, let the response surface function be given by the formula (7). An increased number of factors at many levels means a large number of experimental trials; the realization of trials
On the search for conditions for production process optimization

in all the experimental area points is impossible because of either the costs of experimental trials or prolonged time of the experiment. In either case, the experimenter's task is to select from among the points of the experimental area of \( n = \prod_{i=1}^{m} n_i \) the possible points which allow one to obtain the best results. The proposed algorithm for determining the points of experimental area consists in defining a confidence area for the response surface function with the use of the estimation of confidence intervals for parameters of response surface functions. If the assumptions of the least squares method have been fulfilled, one may use the estimation of the confidence interval for parameter \( \hat{\beta}_i \) as follows (Zieliński, 2007):

\[
\left( \hat{\beta}_i - t_{a,n-p} s \sqrt{v_{ii}}, \hat{\beta}_i + t_{a,n-p} s \sqrt{v_{ii}} \right),
\]

where

\[
s = \sqrt{\frac{1}{n-1} \sum_{i=1}^{n} (y_i - \bar{y})^2}
\]

\( t_{a,n-p} \) – quantile of Student's t-distribution with \( n - p \) degrees of freedom,

\( v_{ii} \) – appropriate element of matrix \( \left( X^T X \right)^{-1} \).

However, if the use of the classical method of estimation of response surface functions is impossible or – in the case of a small number of observations – unreliable, one should use the bootstrap confidence intervals (Domański, Pruska, 2000). A bootstrap distribution of each \( \hat{\beta}_i \) parameter is obtained as a result of the use of the bootstrap estimation of response surface function. Consequently, the confidence interval, with confidence level at \( 1 - \alpha \) , is defined as follows (Kończak, 2013):

\[
(\hat{\beta}_{i,a/2}^*, \hat{\beta}_{i,1-a/2}^*),
\]

where \( \hat{\beta}_{i,\gamma}^* \) – quantile of \( \gamma \) order of the empirical distribution of \( \hat{\beta}_i \) parameter.

On the basis of the confidence intervals for the response surface parameters, one may determine the upper \( \tilde{y}_U(x) \) and lower \( \tilde{y}_L(x) \) estimations of the response surface function. Then, from all the points of the experimental area, the experimenter ought to select the points for which the values \( |\tilde{y}(x) - \tilde{y}_U(x)| \) and \( |\tilde{y}(x) - \tilde{y}_L(x)| \) are the lowest.
4.2. The use of the proposed algorithm

T. P. Ryan (2007) considers an experiment which includes two factors – Supplement \((X_1)\) and Whey \((X_2)\) – and the response variable Quality \((Y)\). The experimental data are presented in Table 1.

<table>
<thead>
<tr>

</tbody>
</table>

For this experimental data, the purpose of the experimenter's research is to select the points of the experimental area in which the values of the estimation of the response surface function are the best according to the proposed algorithm. It has been established that it is possible to conduct only four experimental trials. In order to present the proposed approach, the classical and bootstrap methods have been used.

Let us assume that the assumptions of the least squares method are fulfilled. Then the estimated response surface function is given in the form of

\[
\tilde{y}(x) = 4.57 - 0.63x_1 + 0.1267x_2 + 0.6767x_1x_2.
\]

According to the proposed scheme, for each parameter of the response surface function the confidence interval (8) was computed. The results are presented in Table 2.

On the basis of the obtained results, the upper and lower bounds of the response surface function are defined respectively as follows:

\[
\tilde{y}_U(x) = 5.171 + 0.5716x_1 + 0.5272x_2 + 1.478x_1x_2,
\]
\[
\tilde{y}_L(x) = 3.97 - 1.8316x_1 - 0.2739x_2 - 0.1244x_1x_2
\]

Then the values of $|\bar{y}_i - \bar{y}_{L,i}|$, $|\bar{y}_i - \bar{y}_{U,i}|$ and $|y_i - \bar{y}_i|$ were computed. The results are presented in Table 3.

Having analyzed the results, one can note that the design of experiment should be defined as follows:

$$P_{MNK} = \{x_1, x_2, x_3, x_5\}.$$
Table 3. Values of appropriate estimations (the classical method)

Then the response surface function can be expressed with the following equation:

$$\tilde{y}^*(x) = 4.527 - 0.634x_1 + 0.125x_2 + 0.6795x_1x_2,$$  \hspace{1cm} (13)

and the upper and lower bounds of the designed response surface function are as follows:

$$\tilde{y}^*_U(x) = 4.6953 - 0.415x_1 + 0.251x_2 + 0.853x_1x_2$$  \hspace{1cm} (14)
\[ \tilde{y}^*_L(x) = 4.459 - 0.851x_1 - 0.0037x_2 - 0.4993x_1x_2. \] (15)

Figure 2 shows the graphical representation of the obtained estimation of the response surface functions.

Source: own elaboration.
Just like with the classical method, for every point of the experimental area the values of $|\tilde{y}_i^* - \tilde{y}_{L,i}^*|$, $|\tilde{y}_i^* - \tilde{y}_{U,i}^*|$ and $|y_i - \tilde{y}_i^*|$ were computed and presented in Table 5.

According to the proposed method of the optimization of product quality, the points in which one ought to conduct the next experimental trials were selected:

$$P_{MB} = \{x_1, x_2, x_3, x_5\}.$$

It is important to notice that this design of experiment involves the same points as the selected design with the classical approach.

On the basis of the results presented in Table 2 and Table 4, one can state that the form of response surface functions (10) and (13) are similar, but the determined confidence intervals for the response surface parameters are narrower in the case where the bootstrap method of the estimation of the response surface function was used. Therefore, more precise estimation of the response surface function can be expected when the bootstrap method is used. These suppositions can be confirmed through comparing the results presented in Table 3 and Table 5. There are comparable differences between the empirical and theoretical values, but the differences between the upper and lower estimations of the response surface function are also lower for the bootstrap method than the least squares method.

Thanks to the use of the proposed scheme for searching for the conditions for the optimization of product quality, the number of experimental trials was reduced, and the relevant characteristics of the results of the manufacturing process were preserved.

5. Conclusions

Design of experiments is one of the tools of statistical quality control allowing one to improve the results of production processes effectively. The theory of the optimization of design of experiments in particular leads to defining the design of experiment which is appropriate because of the optimal criterion or conditions of product quality. An important issue in terms of planning the results of production processes is taking into account the economic aspect of design of experiments.

The proposed algorithm for searching for the conditions for the optimization of manufacturing processes allows one to determine design of experiments for a determined number of experimental trials. Moreover, this paper
presents the possibility of using the bootstrap method. In this approach, the estimated confidence area for a response surface function is characterized by greater precision in comparison to the classical approach. The possibilities of the presented method of searching for the optimal conditions for manufacturing processes result in reductions in experiment cost and duration, and also allow one to maintain the proper technological level of production processes.
